

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

Conclusions.

INTRODUCTION

The most important question confronting the highway engineer is the type of road to build that will give the maximum amount of service for the money, and, considering the different conditions to which the road will be subjected.

This question of the proper improvement of roads is of ancient origin. Extensive military roads radiating from Rome were constructed and among these, "The Appian Way," having a length of 360 miles, can be found today in fairly well-preserved condition.

Farmers throughout the country have for a period of years constructed and maintained their town highways. The road commissioner was elected, and he superintended the construction work. Each tax-payer worked out his share of assessment by furnishing teams, materials and services. This method of construction was never satisfactory, and upon the advent of the swiftly moving automobile became unbearable. The automobile used for pleasure, or the heavily loaded truck, the motor cycle and to some extent iron-shod horses hauling heavily loaded wagons with narrow tires are the agents which make maintenance costs a large item in highway construction.

Because of the fact that everyone will keep the center of the road except on passing, the old form of earth and macadam roads are soon rutted along these paths. Water collects in these ruts and finds its way to the foundation, thereby causing softening of the sub-grade and heavy maintenance costs.

The United States Office of Goods Roads have issued a report covering roads built in the United States up to 1909. Out of 2,199,645 miles of highways, only 8.66% were improved. During 1910 State aid and construction located 4,278 miles of improvement. In 1911 the available data shows that from the 49 states and territories, 13 gave aid on their roads, two gave convict services, 5 gave engineering service, 1 state gave convict broken stone, 28 gave more or less direct aid.

The number of automobiles in the United States in 1912, including commercial vehicles, was 1,013,975. The total number of machines in use during the same time was nearly 1,000,000. The total mileage of improved roads at the close of 1912 was approximately 222,081. That is, there were nearly five automobiles to each mile of improved road.¹

The automobile traffic in all forms is rapidly increasing, as is shown by the following table.

TABLE I ²
TRAFFIC CENSUS IN MASSACHUSETTS

YEAR	NO. STATIONS	AVERAGE NO. OF VEHICLES	% TOTAL VEHICLES PER DAY
1909	238	96.1	39
1912	156	222	63

This shows an increase in automobile traffic of 131% in three years.

1. U.S. Dept. Agriculture, Office of Public Roads, Bulletin #48
2. Ibid.,

EFFECT OF MODERN TRAFFIC ON MACADAM HIGHWAYS

The waterbound macadam is the most easily disintegrated by the action of motor traffic. The suction of the pneumatic tires, and the propelling action of their driving wheels, loosens the binder of the road. The dust is drawn up and blown from the road by a strong draught passing under the car.

With the bituminous type of macadam the effect is not so marked or rapid. The bituminous materials bind the courses of stone together more securely. The action of the automobile tire is to first remove the wearing coat of sand or small pebbles. The top stone are later left exposed, making a very rough surface to ride over.

Many methods have been used in spreading bituminous materials on the road surface. Mechanical spreaders have been ^{un}used and have proved satisfactory. The regulation of the flow of binder has given very serious trouble. It is essential in spreading binder that the machine move at a uniform rate of speed. This is impossible with the use of horses, as propelling forces. Also dirt or other foreign matter often found in the barrels fills up the valves and give an unequal distribution of material.

Hand spreading is now used extensively in New York State with fairly good results. One side of the stone is well covered with material while the side away from the spreader is somewhat slighted.

It is very difficult to obtain an equal distribution of

of bituminous material. Places are left where very little binder is spread. Ravelling will start there, and water will eventually reach below the surface forming a soft place, needing prompt repair.

Oil macadam has been constructed in New York State with very poor results. The additional cost over waterbound macadam with little increased value as to life does not warrant its adoption as a permanent road. It has the advantage of being dustless, but as in the case of waterbound macadam, the automobile soon destroys the wearing course leaving the top stone exposed to the weather.

EXPERIMENTATION

Much experimentation on macadam and concrete has been carried on by the United States and State governments. Probably the most thorough investigation of macadam and concrete highways has been carried on by the United States Office of Good Roads at Chevy Chase.¹ Here the traffic was heavy, composed both of heavily loaded traffic cars and also pleasure automobiles.

The road was first constructed in 1911. Several sections of bituminous and waterbound macadam were constructed. No available data is on hand at present as to the wear of these roads.

The concrete road was laid during the last few months and was composed of experiments I and II, Bituminous concrete sec-
1. Cement Era, Oct. 1913.

tions and experiment III concrete mixed with oil. No expansion joints were used, and road made twenty feet in width and six inch average depth. The subgrade of the road was made to conform to the finished surface. The concrete mixture, 1:1½:3, was thoroughly tamped into place. The sand used in the mixture was required to pass a ½ inch screen and gravel ½" to 1½" inclusive. The limestone was the portion retained by ½" screen and left by ¾" screen. Concrete was covered with sand and kept wet for seven days. The highway was then thoroughly cleaned and a coat of bitumen 1/3 to 1/2 gallon per square yard spread on the clean surface.

Five pints of oil per bag of cement was used in the oil concrete. Cracks occurred in the concrete approximately 23 feet apart. The gravel aggregate contained more cracks than crushed stone.

The oil weakens the strength of the concrete but makes it more impervious.

The conclusions drawn from oil concrete at present show that this method of construction has no advantage that would warrant its adoption.

EXPERIMENTAL WATER BOUND MACADAM²

HUDSON AVENUE, MONROE COUNTY,
N.Y.

This road, .65 miles in length, was constructed in 1900. The surface was 16 feet wide with foundation course 4 inches thick and a top course of crushed trap rock 2 inches in thickness. The road cost \$7,242.67 to improve or \$11,370 per mile. The traffic carried by this road was exceedingly heavy, and it was necessary to repair the road from time to time. The total cost of maintenance has been \$1,045 per mile per year.

EXPERIMENTAL PAVEMENT CONSTRUCTED ACCORDING TO
HASSAM IDEA³

Old macadam roadbed spiked and reshaped stone was then spread to the depth of 8 inches. It was properly rolled, and the grout used being 2 bags of cement to 2 bags of sand, and 20 gallons of water. The pavement was 14 feet wide and cost

1. Massachusetts Highway Commission, Report of 1901.
2. N.Y.State Commission of Highways, 1911.
3. N.Y.State Commission of Highways, 1910.

\$1.50 per square yard, without expansion joints. During the cold weather cracks appeared across the roadway every 50 to 100 feet. The former waterbound macadam roadway was rutted considerably and crown badly worn when Hassam pavement was constructed.

DEVELOPMENT OF CONCRETE ROADS

History

The first pavement on record was laid in Bellefontaine, Ohio, in 1893-1894. It was laid on two wide streets surrounding the court house square. The base of 4 inches of concrete, 1 part of cement to 4 parts of gravel. A two inch top course 1 part of cement to 1 part of sand. No expansion joints were used, but the pavement was cut into blocks of 5 foot square. Considerable wear developed along the longitudinal joints. The total maintenance to date has been \$200.00. Cost \$2.25 per square yard.

Following is a tabular digest of important concrete pavements constructed in United States,

WAYNE COUNTY ROADS

In the year 1893 the constitution of Michigan was amended after which a county road law was adopted making the county instead of the township the unit of building and maintaining roads.

In 1909 a tax of $1/4$ mill was imposed giving \$85,000 to be used in the construction of roads. This was followed the next year by a $1/3$ mill tax, and in 1911 by a $1/2$ mill tax. Wayne County then bonded itself for \$2,000,000 to be spent for road purposes in five years.

First only waterbound macadam or gravel roads were constructed, but these were soon found unsatisfactory. An investigation was then made for the purpose of discovering any available and satisfactory road metal. A study of the experience of smaller towns with their side-walks, bridge floors and other concrete structures was made with the result that concrete was finally adopted.

In 1909 concrete was substituted for macadam and used in experimental work. The first experimental road was constructed in two courses. The bottom course was of a $1:2\frac{1}{2}:5$ mixture, and 4" in thickness. The wearing coat was made $2\frac{1}{2}$ " thick of a $1:2:3$ mixture. The road was built on sub-soil of gravel.

The second experiment was constructed under the specifications given above, but on a clay sub-soil.

The following statement gives a list of the concrete roads constructed in Wayne County in the year 1910:

TABLE V.¹CONCRETE ROADS CONSTRUCTED IN WAYNE COUNTY

The only repair required on these concrete roads has been refilling of contraction joints with tar and sand on the roads first constructed. These joints were not protected by armor plate. The cost of maintenance up to that time would not exceed \$100.

In 1913 there were approximately 20 miles of concrete roads laid using the standard specifications of a 1:1½:3 mixture, 1 course construction, using a crown of 1/100th of the width of the road metal. The shoulders are four feet in

1. Sixth Annual Report of Wayne County.

width and constructed of gravel. The gravel is placed in 3 inch layers and each is thoroughly compacted by rolling before the succeeding one is placed. After at least three weeks the shoulders are further consolidated by a roller as approved by the Board of Commissioners. There is 820,000 square yards of concrete pavement in Wayne County at present.

The defects appear on fills or in cuts, due either to settlement or water or frost in sub-grade.

Holes are due to courser material collecting in small nests and having insufficient mortar to bind together.

More general disintegration due to too fast drying or to freezing while setting.

1. Paper read by F.F. Rogers, Michigan Highway Com. at American Road Congress at Detroit.

The forces which cause cracks are:

- (a) Temperature variation.
- (b) Extraordinary heavy loads.
- (c) Unequal settlement.

Temperature does not seem to be the cause, because if this were so all slabs would have approximately the same number of cracks. This is not so.

If heavy loads caused the defective work, there would be a large number of continuous cracked slabs. There is no evidence of this in Wayne County.

Mr. Johnson believes that defects are due to settlement of foundation combined with temperature and load stresses. He states that the cracks in a concrete road are a minute affair. They are easily and cheaply repaired by filling them with pitch. This presents an unbroken road surface.¹

Up to the present time, the defects noted, except the pitted conditions of the concrete roads (surfaced with refined tar and fine gravel) are not serious and have not caused any additional cost of upkeep.²

In the past two years the expansion joints on all the old work, whether reinforced or not, have been recoated with refined tar and sand once a year. The cost has ranged from \$50 to \$100 per mile per year.

1..A.N.Johnson, Engineering-Contracting, Oct. 22, 1913.

2. F.F.Rogers, Engineering-Contracting, Oct. 22, 1913.

TYPES OF CONCRETE PAVEMENTS

- (1) Hassam Compressed Concrete
- (2) Concrete Cube Pavement.
- (3) Concrete Simple Unit or Layer
- (4) Simple Concrete Covered With Some Form of Bitumen.
- (5) Reinforced.
- (6) Dollarway.

1. HASSAM COMPRESSED CONCRETE

The Hassam pavement is constructed on a properly constructed subgrade. First a layer of proportioned stone is laid to a depth of 6 inches, and compacted by thorough rolling. A grout composed of 1 part cement to 2 parts sand is then poured upon the stone until the grout flushes to the top. A layer of pea stone is next evenly spread over the grouted layer and the rolling continued until the grout flushes to the surface.

On top of this surface is spread a 2 inch layer of trap rock. This is rolled and grouted as the bottom course except that a thin grout of 1 part cement to 2 parts sand is used.

A finishing coat composed of 1 part cement, 1 part sand and 1 part pea size trap rock is mixed thick and broomed into the voids. Rolling is continued until the pavement has a smooth surface.

The following table gives several examples of the Hassam type of construction.

TABLE IX.¹

CITY	YEAR BUILT	SQUARE YARDS	THICKNESS INCHES	COST PER SQ.YD.
Niagara Falls, N.Y.	1911	1,200	6"	\$2.00

Niagara Falls, N.Y.	1912	32,300	7"	2.00

2. CONCRETE CUBE PAVEMENT

The roadway is first properly graded and drained, and a sand cushion of 1/4 to 1/2 inch in depth spread smoothly over the finished subgrade. Two inch concrete cubes, properly made and cured, are laid on this sand cushion. These cubes are then properly rolled to give an even and true surface. A sand filler is next applied and broomed into the joints. Four foot shoulders are constructed to hold the cubes from spreading.

Cubes for concrete pavements should be dried in racks for 24 hours and seasoned for three months before they are used in

1. Concrete Highways, Assn. of American Portland Cement Mfgs. 1913.

pavement construction.

A concrete cube highway was constructed near Rochester, N.Y., in 1909. 730,000 2-inch gravel concrete cubes were used in this pavement. The roadway was 15 feet wide and had a crown of $1/2$ inch per foot of width. The road was subjected to very heavy and mixed traffic, and at the end of two years large areas of the pavement failed. There were 1,700 square yards constructed at a cost of 51¢ per square yard.¹

3. CONCRETE SIMPLE UNIT OR LAYER TYPE

After the sub-grade has been graded to the proper elevation, compacted well by rolling and the drainage facilities properly treated, the roadway is ready for depositing the concrete.

The sub-grade is first watered so that the concrete will not be dried out rapidly when first deposited. The concrete is then mixed in the proper proportions and deposited by successive batches on the roadway. Sufficient water should be used to insure easy spreading with a template, but not to cause a separation of aggregate and mortar.

The concrete is brought to the proper grade by means of a template. The surface is then finished properly from a bridge. This compacts the surface and leaves it free from depressions or inequalities.

When the concrete has hardened sufficiently to prevent pitting, it is covered with a canvas to prevent rapid drying

1. Engineering Record,

out. This is later removed and a layer of earth or sand is spread over the pavement and kept wet and free from traffic for ten days.

Table X, following, gives several examples of the simple unit type of pavement.

TABLE X.¹

LOCATION	YEAR BUILT	SQUARE YARDS	THICKNESS INCHES	PROPORTIONS	COST SQ. YD.
Burlingame to San Francisco	1912	76,000	5"	1:3:6	\$ 0.67½
Highland Park, Ill.	1912	15,000	5" & 7"	1:2:3½	1.01
Atlantic, Ia.	1912	13,400	6" & 7"	1:2:2	1.12
Bettendorf, Ia.	1911	29,000	6"	1:2:4	0.85
Burlington, Ia.	1913	34,400	6"	1:2:3	1.17
Kansas City, Ka.	1912	16,400	6"	1:2:4	1.00
Grand Haven, Mich.	1913	13,300	7"	1:4 excl. grading	1.05
Bemidge, Minn.	1912	19,800	5"	1:3½	1.05

The preparation of the sub-grade for the layer type is the same as for the one course construction. The concrete is mixed in the specified proportions, a 1:2½:5 being considered advisable. Successive batches of concrete shall be deposited immediately on the finished sub-grade. The concrete is well tamped to an elevation which will bring the top surfacing up to the finished grade.

The wearing course is mixed in the proper proportions,

1. Concrete Highways, Assn. American Portland Cement Mfgs. 1918.

one of cement to two parts of aggregate being found satisfactory. This wearing surface shall be deposited on the bottom course before this has set up hard enough to prevent a bond between surfaces. It should not be deposited later than fifty minutes after the bottom course has been laid. The surface is finished and cured as in the one course type of construction.

Milwaukee County has laid one course construction extensively in 1911, 1912 and 1913. The mixture used was 1:2; $3\frac{1}{2}$ and the widths varied, being 12, 16 and 18 feet. These roads have five foot gravel shoulders none of which are rolled. In sand these concrete roads are seven inches at the center and six inches at the side. In clay or loam the depth in the center is 8 inches with 7 inches at the side. One of these roads known as the Blue Mounds Road has been pronounced by experts as the best type of concrete construction in the country.

The average costs have been \$1.10 per square yard for concrete and \$1.22 per square yard for road including shoulders and grading.

Richmond, Ind., laid 34400 square yards of two-course construction at a cost of \$1.48 per square yard. No maintenance costs have been incurred on any of Richmond's pavements to date. Many examples are found under the history of concrete pavements.

4. SIMPLE CONCRETE COVERED WITH SOME FORM OF BITUMEN

The simple concrete is laid as described and the surface thoroughly cleaned and dried. Bitumen is then applied to the pavement to the amount of $1/2$ gallon per square yard. Hot sand is spread evenly over the pavement and a tandem roller is used to compact this material. More sand is added until all the bitumen is taken up. The total depth of the sand is from $3/8$ to $1/2$ inch.

At Newark, N.J., up until 1912 there is on record approximately 120,000 square yards of bituminous concrete pavements, using an average of 6" in depth and costing \$2.13 per square yard.

5. REINFORCED CONCRETE PAVEMENTS

Reinforced concrete pavements are built of either the one or two course construction. After the base of the two-course construction is completed, the reinforcing metal is laid directly upon the bottom course and lightly tamped, so as to be about half embedded in the concrete.

In the one-course construction the concrete, as in the simple type, is leveled off to a depth of two feet below the finished surface of the roadway. The reinforcing metal is laid and the wearing course of $1:1\frac{1}{2}:3$ mixture is placed, finished and cured as in the simple type of construction.

The following table gives examples of reinforced concrete pavements constructed in Fond du Lac, Wis.

TABLE XI.

NAME OF STREET : SQUARE YARDS : PRICE		
Merrill	: 8608	: \$1.24
Alcott	: 1897	: 1.20

May 22, 1913.

CHAPTER III

DESIGN

Before a road is designed or constructed it is necessary to know under what conditions of traffic it is to be used. A traffic census should be taken and inquiry made of the people living near by.

In order to obtain a fair report, a normal summer traffic, an abnormal summer traffic, and a normal winter traffic should be taken.

1st. Traffic reports should be taken six or seven consecutive days.

2nd. Distributing the recording days throughout a season. Monday of the first week, Tuesday of the second week, etc.

3rd. Traffic taken for a season from April to October, inclusive. These traffic reports to be taken for four periods of three days each.

One report taken in April, May and June, one in July, one in August, and one in September or October.

The first two plans would give only an abnormal or normal report, depending upon the month and weather conditions. The third plan is the most practical, efficient, and gives more nearly an average result.

The following are the most essential considerations which should govern the planning of an individual road or a complete highway system:

I. The road should be as direct as the topography and limiting grades permit.

II. Trunk lines should form the basis of a complete

road system.

III. Detours from the general direction of trunk lines to reach unimportant towns are not justified. Such towns can be served by branch lines.

IV. The principal streets of a city should form a part of the trunk system in which the city belongs. Facility of movement between city and surrounding country is essential.

V. Roads should increase as they approach important towns. This will save future expense in widening the streets.¹

VI. At crossings or junctions of rural highways sufficient space should be added to the road to afford a view of approaching vehicles.¹

WIDTH

The Wisconsin Highway Commission has found that for very heavily traveled sections the 14 or 16 foot roadway is desirable, while in localities where traffic is light a 9 foot roadway is sufficient. See Plates I and II.

TABLE XIII
TRAFFIC CONDITIONS

CHARACTER OF VEHICLE	MILES TRAVELED	LIGHT TEAMS MET	LOADED TEAMS MET	MILES TRAVELED PER LOADED TEAM	MILES TRAVELED PER LIGHT TEAM	MILES TRAVELED LOADS & LIGHT
Light	230	66	142	3½	1-2/3	1-1/10
Loaded	104	32	53	3½	2	1-1/5
Totals	334	98	195	3-2/5	1-7/10	1-1/7

By the table we see that a loaded vehicle travels 3½ miles before meeting a loaded team, and 2 miles before meeting a light team.

1. Engr.-Contracting, Sept. 10, 1913.

With solid and well-made shoulders two vehicles can pass easily on a 9 foot roadway. Vehicles must slow down on a narrow roadway when passing. This is an advantage in building narrow roadways, as it saves maintenance costs and loss of life.

When important routes lead out of cities a 16 foot or even an 18 foot roadway is advisable until all feeder roads are passed. The 9 foot width will amply serve the purpose on branch roads and 14 foot on trunk lines.

CROWN

The crown should be from $1/8$ to $1/4$ of an inch to the foot of roadway. The Wayne County roads are now built with a crown of $1/100$ th of total width of concrete, while the Wisconsin Highway Commission favors a crown of two inches on all roadways. The crown should be only sufficient to carry off all surface water.

The following table gives the crown of streets in various American Cities.

TABLE XIV¹

TABLE SHOWING CROWN OF STREETS IN VARIOUS AMERICAN CITIES

Fond du Lac, Wis.	27	4	1:90

1. Compiled from data received from Universal Portland Cement.

Current practice favors a maximum thickness at center of 8 inches, and a minimum of 7 inches. The sides of the pavement vary from 5 to 6 inches, in depth. These thicknesses depend upon the soil conditions and the traffic. On heavily traveled roads an average depth of 7 inches should be used, while the 6 inch depth is suitable for lighter traveled roads. In clay an average of 7 inches of concrete should be used while in sand where we obtain good drainage 6 inches is suitable.

EXPANSION JOINTS

Expansion joints have given the most trouble in concrete highway construction. Their width, length of sections and protection have been varied in experimental work.

Concrete is known to shrink $\frac{3}{4}$ of an inch to the 100 feet in 6 months. This is as much as caused by a temperature change of over 100 degrees Fahrenheit. If this sudden drying out could be prevented many of these defects would be eliminated.

The average coefficient of expansion of concrete is about 0.000005 per degree Fahrenheit. In Wisconsin with a variation of 100 degrees Fahrenheit the theoretical width of joints for various spacings would be as is shown in the following table.

TABLE XV.

JOINT SPACING FEET	:	WIDTH OF JOINT INCHES
30	:	3/16
40	:	1/4
50	:	1/3
100	:	5/8
150	:	3/4

Wayne County has experimented with several types of joints; two thicknesses of three-ply tar paper separated with a pine board, asphalt, still wax and pitch. The Baker armor plate has proved the most satisfactory and is used exclusively. These plates are of soft steel 3/16th of an inch thick and 3 inches wide. These are curved to conform with the finished surface of the roadway. Between the plates is placed 3 thicknesses of asphalt felt about 1/4 of an inch in thickness. These plates are anchored to the concrete by shearing out parts of the member at regular intervals.

COST OF STEEL PROTECTION EXPANSION JOINTS

Steel plates cost approximately 13¢ per foot of joint, f.o.b. points in Wisconsin.

Asphalt felt composition filler costs 1¢ per foot, f.o.b. points on railroad.

The entire time of 2 laborers will be required to do the joint work when from 200 feet or more of joints are laid in a

10 hour day.

Labor of filling joints . . 1-3/4¢ to 2¢ per foot of joint
 Asphalt heated , 2¢ to 3¢ per foot of joint.

When asphalt felt is used without metal protection the cost will be approximately that of protected joints with protection material deducted.

Wayne County expansion joints add 5¢ per square yard to the cost of the pavement.

MIXTURE

Concrete must be very dense and be able to withstand shearing and compressive and tensile stresses. A 1:1½:3 mixture of concrete has proven satisfactory and is used exclusively by Wayne County, which has constructed the greatest mileage of concrete roads. Wisconsin Highway Commission favor a 1:2:3½ concrete.

Concrete must be very dense so that no water will find its way to the subgrade. Too large a percentage of water is not recommended as the maximum strength of concrete is materially lessened.

MATERIALS.

It is necessary to use a concrete whose mortar content is rich in cement in order that a sound and strong concrete may be obtained. In general, limestone and similar soft rocks are not satisfactory, while quartzites and flint gravels are excellent.

Concrete pavements cannot go far wrong if the following requirements are adhered to.

(1) Selection of Portland cement conforming to the specifications of the American Society for Testing Materials.

(2) Sand, clean, sharp, coarse and well graded; 5% of finely divided clay is allowed.

Experiments at the University of Illinois show that the strength of concrete is not materially lessened by even 6% of finely divided clay. The cost of cleaning gravel is a large item and it is more economical to use a small percentage more of concrete.¹

(3) Coarse Aggregate: Clean, hard and sound rock, gravel of good quality, or hard dense crushed furnace slag is recommended. Water should be free from strong acid or alkalies and the concrete mixed fairly wet.

SHOULDERS

Shoulders for concrete roads should be constructed of gravel containing sufficient binding materials or crushed limestone. The North Fond du Lac concrete road was constructed with 3 foot gravel shoulders on 14 foot road and 5½ foot on the 9 foot roadway. They were made flush with the concrete and sloped off to 0 at shoulder width. The present practice in Wisconsin is to use 5 foot shoulders not rolled on all roads. Wayne County, Michigan, constructs shoulders 3 feet in width and from 3 to 7 inches in depth, using either limestone or gravel.

1. Cement & Engr. News, Oct. 1913.

The aim of the Wisconsin Highway Commission is to limit the grades on the roads to 6%. Most grades on through roads average 4 to $4\frac{1}{2}\%$. Concrete is adaptable to all grades and alignments.

CHAPTER IV

CONSTRUCTION

After the proper appropriation of money for the assigned road has been completed, the preliminary survey is made. Level and transit parties are sent into the field to run grades and line on existing roadway. These notes with suggestions as to local conditions of drainage, existing culverts, bridges and soil are forwarded to the highway office. The notes are plotted up, and new location of line and grade fitted, so as to give a proper distribution of material and within ruling grades.

The final survey party is then sent into the field, and the construction grades and line staked out. These stakes are offset from the new center line of the highway, so as not to be disturbed during construction. They are placed 50 feet apart on tangent and usually 25 feet apart on curves.

It has been found convenient to place these stakes near fences so as not to be disturbed by plowing, mowing or pasturage of cattle.

Even with the best grade of materials and design, a concrete road must have the best possible construction and inspection to prove satisfactory.

PLANT

The size of the plant used in any case depends upon the amount of work and time required to complete the construction.

According to good practice, a fair arrangement of plant seems to be the following:¹

- 1. Foreman
- 3 men finishing sub-grade.
- 1 man preparing joints.
- 2 form setters
- 6 loading wheelbarrows
- 2 handling cement
- 1 engineman
- 1 hoistman
- 1 man at concrete spout
- 2 striking off concrete
- 1 finishing - trimming edges
- 1 general utility man.
- 1 water boy

Total 26 men - expense \$63.00 per day

- 1 team hauling water
- 1 team hauling cement
- 1 steam mixer

This plant will be capable of constructing 600 square yards of pavement 6" in thickness.

SUB-GRADE

The preparation of the sub-grade demands careful consideration. The sub-grade must be first brought as near to grade as possible, so that materials can be hauled onto the roadbed. If the grading is heavy, it is well to use teams, plows and scrapers, or a steam shovel may be used economically, if the cut contains a large yardage. Most of the work in Wisconsin can be done economically by pick and shovel, a plow and sufficient teams and dump wagons, as most of the roads are laid practically upon the old roadbed. The elevations are taken from the stakes and distance to subgrade equal to depth of pavement measured down from this point.

As the improvement of the road attracts traffic and thereby increases the stresses in the sub-grade, every weak place must be remedied. Concrete has less resiliency than most other types of highway materials, and the stresses resulting from traffic are greatly increased. The brittle character of concrete demands an even, sound and well-compacted foundations. Depressions in the foundation cause settlement of the concrete and consequently cracks.

The center of the old roadway is generally well hardened by traffic while the sides are less compacted. It is necessary in this case to supply new material to the sides and compact it thoroughly, thereby approximating a foundation of uniform strength.

If the road is built on an old macadam or stone foundation, and the new alignment does not coincide with the old, the road should be harrowed, leveled and thoroughly rolled to give a uniform bearing surface. All soft places, stumps and boulders should be removed to a depth of at least 6 inches below the finished sub-grade.

DRAINAGE

Good drainage is very essential to concrete road construction. It is necessary that all water be carried to the ditches and not left to seep from shoulders under the road metal. Many different plans for drainage have been experimented with, and proven satisfactory.

The simple type of drainage is the side ditches running parallel to the center line of the highway. They are usually built at a minimum 18 inches to 24 inches below the grade of the finished road.

When the roadway is on a side hill a 4 inch tile drain is laid 3 feet below the center of the sub-grade. This trench is filled with a coarse material for 9 inches, with hay or straw for 3 inches, and the remainder of three feet with gravel or coarse broken stone. In cuts two drains are used one on either side of the roadway. This type of construction is used in Wisconsin at present.

The following drainage system was advocated by the Third International Road Congress.

Water often seeps from the shoulders under the concrete through a plane between the shoulder and the road metal. A shallow drain having a width and depth equal to a shovel is excavated under both edges of the pavement. This is filled with coarse material, so as to form a blind drain. At 40 or 50 feet intervals lateral blind drains are constructed to carry this seepage water to the side ditches.

CONSTRUCTION PROPER

After the sub-grade and drainage have been properly provided for, the concrete is laid. All irregularities in the sub-grade are levelled and the side forms staked to the proper grade. The proper mixture specified should be measured

in cubic foot boxes to guide the laborers in forming the proper proportions.

The materials are placed in the mixer and water added to give a fairly wet mixture. It is then deposited upon the finished sub-grade. The concrete is immediately finished to the proper grade by means of workmen using a strike-off board conforming to the crown of the finished roadway.

When the concrete is dumped upon the roadway, the mortar part usually flows to the edge of the pile, leaving a core of aggregate with insufficient binding material. This should be remedied by distributing the rest of the aggregate by means of rakes and mixing it with the mortar.

The surface finish is then applied by men working from a bridge resting on the side forms. The surface is floated generally with a large wooden tool so as to smooth all irregularities and leave it a little rough. If a rough finish is wished, a coarse wooden broom may be drawn across the pavement while working from the bridge. This applies to one course construction which has been generally considered the most practical and most universally constructed at present.

PROTECTION

As soon as the pavement has started to set up a canvas covering should be spread over the same. This is left until earth can be spread over the surface without injury to the concrete. It is then covered with a coat of earth, sand, sawdust or other available material, and kept moistened for

a period of ten days. The covering coat is then removed and the pavement cleaned, surfaced if called for, and opened to traffic.

CHAPTER V.

GEOLOGY¹

The rocks of the State of Wisconsin are very old. Probably the building of the state was completed in the Devonian period, as no rocks of later periods are found within its borders. The glacial period came a few thousand years ago, and with these glaciers was brought a thin sheet of earth which was spread more or less evenly over the land to the south.

The surface of the State was divided by glaciers into two great slopes, Northern and Southern. The northern is sharp and relatively steep, sending the waters into Lake Michigan. The southern slope is much longer and more gentle. It carries on its surface the rivers which drain south into the Mississippi and southeast into Lake Michigan.

Diagonally across the southern slope from the northeast to the southwest extends a great shallow valley. This has played an important part in the history and commercial development of the state.

Across the central portion of the state from the east to the west is a low lying sandstone area. This is less fertile in places than the rest of the state. It is the receiving station of the water which supplies the artesian wells of southern Wisconsin.

North of this low sand stone area lies the highland region of igneous rock, overlying clay deposits of glacial origin. This has retained in many places water to form lakes

1. Case, Wisconsin Geology and Physical Geography.

and swamps.

South of the great sandstone area rocks and soil are more varied.

The glacier moved over the state in succession of advances and retreats, leaving traces which can be easily distinguished today. The unstratified deposits or moraines cover all of Wisconsin except the Driftless area. The stratified drift are found in three different forms in the state, Kame, Overwash plains, and lake bottoms. These contain the sand and gravel deposits.

Gravel and crushed stone are found at all parts of the state in great abundance.

In general the driftless area and a considerable part of the drift covered areas of southeastern Wisconsin is covered with a clay loam. This is derived from decomposition of limestone and accumulation of residual clay.

The central and western parts of the state are underlain by Potsdam and St. Peter sandstone. The soil is of a sandy loam, except where the later drift deposits have covered the true soil.

In the belt extending northeast and southwest in the Green Bay lowlands, underlain by Cincinnati shale, the soil is clay. This contains a considerable amount of sand.

Bordering the Great Lakes, there is a heavy deposit of red clay. This is mixed with sufficient lime to form a marly clay soil of heavy character.

Plate III shows the soils of Wisconsin.

CHAPTER VI

WISCONSIN'S FACILITIES FOR ROAD WORK

The legislature of 1911 passed a law in 1911 creating a State Highway Commission. An annual appropriation of \$350,000 was provided for state aid in 1912 and the succeeding years.

The governor of the State advised by the senate was given the power to appoint three commissioners, who are to hold office for two years. There are two other members on the commission, an ex-officio member, the state geologist, and the dean of the College of Engineering. A highway and bridge engineer were also employed.

There are very good railroad facilities in the state. All gravel and stone companies have ready access to all parts of the state. The railroads will transport road materials used in the construction of highways at a freight rate of one-half cent per ton per mile.

Wisconsin is not a prairie state, although nearly one-half of its area is approximately level. The balance is a rolling country with only low hills and no mountainous or rugged areas.¹

The area composed of hills over 300 feet in height is not more than 5% of the total area of the state. Forty per cent is level upland, and about 50% is rolling country.

A wide and comparatively flat highland extends over the

1. Bulletin Wis. Geol. & Nat. Hist. Survey, NO. I, 1898.

the northern part of the state. This divide varies from 1000 to 1900 feet in height. About 9% of the total area belongs to the Lake Superior watershed and the remainder to the broad southeast, south and southwest slopes.¹

1. Bulletin, Wisconsin Geol. & Nat. Hist. Survey, No. 20.

CHAPTER VII

CONCRETE EXPERIENCE

Wisconsin has not had the experience in concrete highways that other states have had. The first concrete highways constructed in Wisconsin were during the spring and summer of 1911 in Milwaukee County, at Fond du Lac and Appleton.

Milwaukee County laid 7 miles of concrete roads in 1911, 22 miles in 1912, and about 22 miles in 1913. These were constructed of the 1:2:3½ mixture and had widths of 12, 16 and 18 feet. All types of construction have 5 foot shoulders not rolled. The depths of concrete were 7" and 8" at the center and 6 and 7" at the sides.

One road was completed late in November of 1911 and this pitted up and was covered with bitumen which peeled off after a short time. No coating of any form is now used on concrete roads built by the state. Contract work has proved a failure, and now all work is constructed on the force-account system.

Milwaukee roads cost approximately \$1.10 per square yard, exclusive of grading, and \$1.22 per square yard including grading. No maintenance costs are recorded as yet on these roads. The roads constructed in 1913 cost from \$1.24 to \$1.72 per square yard, depending upon local conditions. Screening of gravel has been no special problem in Milwaukee County.

Wayne County roads have been thoroughly discussed, and from the small amount of expenditure for maintenance, have certainly proven satisfactory.

On the Fond du Lac - Oshkosh Road some defective slabs developed. The cause of these defects was not due to mixture, design or supervision, but to a large percentage of clay which became imbedded in the mixture.

The Waukesha gravel was spread in piles in the center of the highway, so that no delay would be encountered when construction began.

Farmers and autoists driving over the road spread the gravel over the soft clay sub-grade. When construction began this was not removed and some defects in the 9 foot roadway developed. These were replaced by new concrete slabs.

As a whole the concrete roads constructed in Wisconsin up to the present time have proven successful and are giving much satisfaction to tourists, farmers and the traveling public.

The following tables are embodied to show the relative costs of construction and maintenance of different types of highways.

TABLE XVI

MAINTENANCE COSTS OF WISCONSIN HIGHWAYS¹

KIND OF CON- STRUCTION	AVERAGE COST : PER SQUARE YARD :	AVERAGE LIFE : YEARS :	AV. COST PER : SQ. YD. PER YR. : REPAIRS

TABLE XXII

REPAIR AND MAINTENANCE EXPENDITURES IN THE STATE
OF MASSACHUSETTS¹

YEAR	:	TOTAL MILES	:	MAINTENANCE COST PER MILE
1905	:	548	:	\$ 105
1906	:	610	:	112
1907	:	655	:	162
1908	:	702	:	327
1909	:	740	:	543
1910	:	784	:	642
1911	:	829	:	647
1912	:	880	:	676

1. Bulletin #48, U.S. Dept. of Agriculture, Office of Public Roads.

CONCLUSIONS

Concrete roads have been successfully constructed in Michigan, Illinois, Iowa and many other western states. Their maintenance costs are a minimum in road construction. New York State is paying approximately \$1,000 per mile per year to maintain their highways, the greater percentage being macadam. Massachusetts paid approximately \$660 per mile per year in 1910, 1911 and 1912.

Waterbound macadam costs on the average \$.65 per square yard, while bituminous macadam will cost approximately 75¢ per square yard. The maintenance on these waterbound roads will however bring the cost equal to the cost of concrete construction in Wisconsin in approximately 5 years time. Bituminous macadam will hold up under traffic much longer. Concrete can be laid in Wisconsin at approximately \$1.25 per square yard, exclusive of grading. The gravel deposits are very numerous and are well distributed throughout the state. Gravel costs from 30¢ to 50¢ per cubic yard at the pit, and the freight by railroad is 1/2¢ per ton per mile. Wisconsin has an abundance of inland lakes and rivers distributed well over the state. The topography of the country is very suitable to concrete road construction, being rolling and flat. The average rainfall is 32 inches and the average range of temperature is 100 degrees Fahrenheit. New York State has a much greater range and their costs of maintenance of all types of macadam have been startling.

Cement production is rapidly increasing and its cost

is decreasing, as shown by the following plates numbered IV and V.

With the experience derived from Wayne County and the roads built in Milwaukee County, Wisconsin cannot err in building concrete roads. The abundance of gravel, water, the topography of the country and the low cost of maintenance, low cost of cement, and proximity of source of supply makes the concrete road the ideal type of construction in Wisconsin.
